Chapter 1

Design Overview

Figure 1.1: Architecture of Information System

Information System of ARC middleware is composed of 3 main parts. The Information System Indexing Services (ISIS) form a set of information containers. Every generic ARC Service pushes information about itself into nearby ISIS container/service hence registering itself to Information System. The information stored in every ISIS is propagated among all ISIS services. Clients can query any nearby ISIS service for registered information in order to perform discovery of services which possess specific properties. Clients can also query ARC Services to obtain more detailed information about Service properties.

Chapter 2

ISIS

2.1 Registration handling

2.1.1 Functionality

The functionality of ISIS is made of two parts. On the one hand they are working as ordinary Web Services, and on the other hand maintain a peer-to-peer network - **ISIS cloud**.

Main functionality of ISIS service visible from outside of ISIS cloud is to accept registration and provide collected information to clients. For that ISIS implements operations described in following section. The single ISIS service accepts Registration Records pushed to it by other services (including ISIS services too) and stores them in local XML database. Stored records can be queried by clients using mandatory and service-specific attributes for selection criteria.

In case of multiple ISIS services they form a peer-to-peer network. Inside that cloud Registration Records are propagated between services in such a way that all ISIS instances continuously try to synchronize their databases.

2.1.2 Interface

Operation Register

Input

Header

RequesterID Identifier of the client.

MessageGenerationTime Time when following set of RegEntry was generated. There may be multiple RegEntry elements.

RegEntry

SrcAdv

Type Type of service being registered. This element is opaque string for now. There shall be service types defined later.

EPR Endpoint Reference of service being registered in terms of WS-Addressing.

SSPair Set of key/value pairs representing service specific information.

MetaSrcAdv

ServiceID Globally unique and persistent identifier of the service.

GenTime (Generation Time) The actual timestamp of information (called wake_up_time in the pseudo code below)

Expiration Validity period of Service Advertisement record.

Output

Fault Optional element describing fault which occurred while performing registration. If missing registration succeeded.

Faults

none No specific faults are defined

This operation is usually called by service which wants to register it's presence in ISIS. This message consists of one or more **Registration Entry** and at most one **Registration Header**. The **Registration Entry**(RegEntry) contains a **Service Advertisement**(SrcAdv) and a corresponding **Service Advertisement Metadata**(MetaSrcAdv). This structure is shown on Figure 2.1.

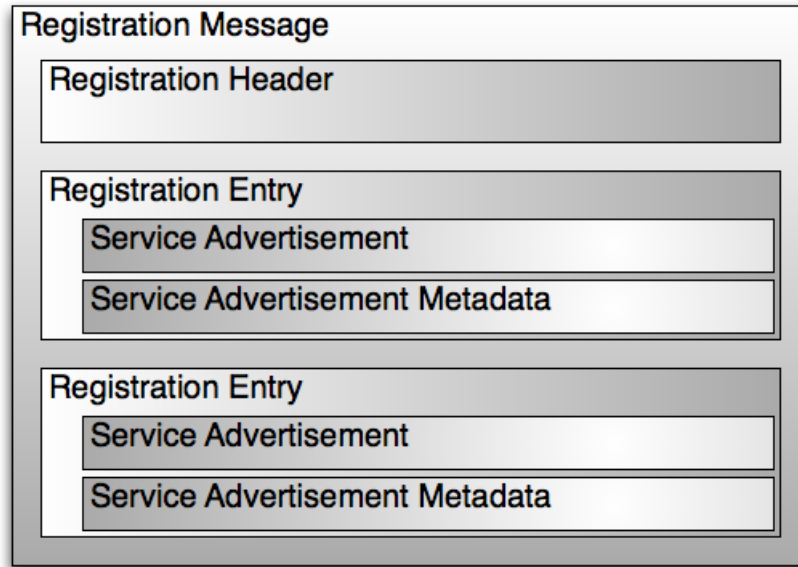

Figure 2.1: Embedded structure of Registration Message

Service must supply mandatory information. Among those the **Endpoint Reference** is used to contact service - only required element is contact URL of service. **Type** specifies kind of service and is used to find out functionality and interface of service. **ServiceID** is used to distinguish between registered services and to deal with case of service changing it's contact URL. For more information about mandatory and optional information see Section 3.1

As result of this operation new Registration Record is stored inside ISIS internal database and eventually propagated to other ISISes. If registration record of same ID already existed it will be renewed.

This operation is also used by ISIS services to propagate Registration Records inside ISIS cloud.

Operation RemoveRegistrations

Input

MessageGenerationtime

ServiceID Multiple identifiers of services, whose records has to be removed.

Output

RemoveRegistrationResponseElement

ServiceID Identifier of service whose record was not removed

Fault Description of failure reason

Faults

none No specific faults are defined

This operation is used to explicitly requesting the removal of zero or more Registration Entries associated with specified ServiceID values stored in the Information System. If corresponding record does not exist it's identifier will be present in response message together with corresponding Fault element.

Operation GetISISList

Input

none

Output

EPR Multiple Endpoint References of known ISIS services

Faults

none No specific faults are defined

In response to this operation the EndpointReferences to all known ISIS services are returned. The operation is used for obtaining a list of known ISIS instances from any particular ISIS. Clients can then use the obtained list to run direct queries against the ISIS instances. The operation is provided for fault tolerance and for providing optional performance boost. This operation returns the known peer-to-peer neighbors. If client is interested in all ISIS instances they can be obtained using the Query operation because they are ordinary services registered into the Information System.

Operation Query

Input

QueryString XPath query expression

Output

any Result of query

Faults

none No specific faults are defined

This operation allows any XPath queries to be performed on stored Registration Records. The records are treated as merged in one XML document with each record being equivalent to **RegEntry** element of **Register** operation. In response all elements produced by XPath query are returned. The purpose of this operation is to make it possible to obtain any kind of information related to the Indexing Database.

2.2 Peer-to-Peer

2.2.1 Functionality

The ISIS nodes are able to organize themselves into a peer-to-peer network by synchronizing the stored replicated database and maintain this synchronicity and the network topology. Every node of this peer-to-peer cloud (that is an ISIS service) has an own PeerID, an identifier only used in this network, made as a hash of its endpoint URL. The members are ordered by this identifier where there is also a sequence defined between them where the successor entity is the ISIS with the smallest PeerID of the greater PeerIDs. This metric is used for defining the neighbour relation that is the base of the inter-peer-to-peer network communication. It is presumed that only registered ISIS nodes can have any role in the cloud.

Connecting to the peer-to-peer network

Every ISIS tries to connect to the network at its startup by accessing the InfoProvider ISIS nodes known from its configuration. The choice from among the few pre-configured InfoProviders is random to achieve as much load-balancing as possible. (In the design it is assumed that a huge amount of ISIS nodes are configured in very similar way, where the InfoProvider ISIS nodes are mainly the same.) If there is no InfoProvider available or nothing is known from the configuration, the node decides to be the first member and to build a new network.

If there are any InfoProvider nodes available the list of member ISIS nodes will be queried and the successor will be defined using the previously mentioned metric. This successor node will help the entering ISIS to connect to the cloud. The new member will use Connect Web Service operation to get the newest version of database stored in the peer-to-peer network, and place its own entries to the cloud by registering them. An initial database synchronization can be achieved using this method.

We can prevent the InfoProvider ISIS nodes from overloading by balancing the operation of database synchronizing being the most costly procedure in the connection phase.

There is also another extension used regarding the InfoProvider ISIS nodes. If a node is not able to connect any of the InfoProviders then it tries to repeat it later. This results that the network is able to fuse two disjoint parts of network when the missing InfoProvider ISIS appears again.

Routing in the peer-to-peer network

We are keeping the databases in synch by passing every Registration and RemoveRegistrations to every node acting in the network. This yields redundancy and the fault tolerant message routing is very important between any two ISIS nodes.

The most important parameter of the network is the *sparsity*. This is an integer not less than 2. It determines the number of neighbors in the function of the actual number of member nodes of the network, where the number of neighbors can change when new members connecting to the network or members leave. A sparse graph can be shaped by choosing a great value for sparsity or a dense one by choosing the less. This value is defined during the design and determines the main properties of the peer-to-peer network.

Figure 2.2: The neighbor connections in the peer-to-peer network in case of sparsity=2

Every node has always exactly $n = \lceil \log_s N \rceil$ neighbors where the N is the number of ISIS nodes registered into the network. The node has as many neighbors as the ISIS nodes with PeerID s^0 -th, s^1 -th ... s^{n-1} -th greater than its own. (For example: There are 19 nodes in this network with sparsity=9. Then the first node has the following neighbors: the 2nd, 3rd, 5th, 9th, and 17th node as seen in figure 2.2.)

There can be exactly n -way redundancy achieved in the system so at most $n - 1$ node can disappear without any serious communication impair. Since there is also an emergency method used trying to deliver messages

even if all neighbors are unavailable, this fault tolerance is greater. With this extension, messages are passed to one of the non-neighbor, yet available ISIS, so the message will surely be delivered to one of the operational node of the network. This solution provides a secure and quite fast solution for the message delivery but has a high communication cost because there are $n * N$ messages necessary in general for every Registration or RemoveRegistrations.

If there is a much greater *sparsity* used, then the number of the expected members decrease, even only to one neighbor. This situation can be seen in Figure 2.3. In this case such functioning is achieved when there are only N (the theoretically minimum) messages traversing in the network at the expense of a slower data propagation.

Figure 2.3: The neighbor connections in the peer-to-peer network in case of sparsity; N

There is a data-driven routing used in the peer-to-peer cloud. It means that the given nodes examine the received Registration Entries then store and forward only those messages that are newer than the already stored version belonging to the same service identifier. If the information in the message is out-of-date then it will be simple dropped. (A Coordinated Universal Time (UTC) standard time and date format is used for the time stamps that is also able to handle the differences originated from the different time zones.) By using this method it is achieved that it is not necessary to store the formerly seen nodes in the messages, but the routing decision that is who to send the message to is based on local information. Since the routing is based on time stamps, it is very important to keep the nodes clock in synch with each other or with an outer reference, say, by using NTP.

Another advantage of this solution is the capability of handling the case of swapped Register and RemoveRegistrations messages. It is possible for a RemoveRegistrations message to forerun a previously generated Register message. This causes just a temporary imprecise entry in the database but the mistake can be quickly fixed and is not much further propagated.

Since the applied routing is based on the state of the messages belonging to some service identifier it is important to keep the fact of message deleting for a while. If a RemoveRegistrations message is received, then the named entry from the database is not removed immediately, just its state changes to *deleted* and a piece of data about it (the service identifier and the deletion time) is kept.

Maintenance of the peer-to-peer network

In the network there are two different maintenance methods needed. On one hand the database have to be periodically cleaned and on the other hand the list of neighbors have always got to be up-to-date.

The database applied in the system is a soft-state database so the entries are *valid* just for a limited time. Without any registration freshening its validity will expire and the state of the entry will change to *expired*. The time of expiration is set in every single message by the registrar entity. The RemoveRegistrations message turn the state of registration entry to *deleted* as it was previously mentioned. The *expired* or *deleted* messages

will be purged in the course of periodical database maintenance. The states of registration entries are shown in Figure 2.4.

Figure 2.4: Registration entry states

The second kind of maintenance is keeping the list of neighbors up-to-date. While receiving even Registration or RemoveRegistrations messages or finding an outdated entry during the periodical database cleaning nodes perform necessary steps to update our list. Since every leaving or entering node influences the neighbor registry of all the other nodes at a high probability the local set of neighbors will be rebuilt in these cases. The modifications are passing locally because these connections are asymmetric so there is no compliance or network communication is needed.

There is no special action done and no additional network traffic needed during the neighbor checking. The fact the node sends periodically messages to every neighbor can be exploited. If the node is not successful in sending its messages to the neighbors after some tries, then the unavailable node will be marked. If every neighbor has been marked then the node changes its PeerID and reconnects to the network if there are any InfoProvider ISIS nodes available.

When a neighbor is unavailable ISIS keeps trying to deliver the message to the successor of the neighbor until either the information is passed to at least one available node or it is diagnosed that all the nodes are unavailable. Here the successor means those nodes that have greater PeerID than the neighbor but less than the next ISIS neighbor.

2.2.2 Interface

Operation Connect

Input

none

Output

RegEntry Multiple **RegEntries** locally stored in the ISIS database

Faults

none No specific faults are defined

This operation allows the ISIS to get the already existing database from the ISIS that helps it to connect the peer-to-peer network. As a second step of the connection the newer **RegEntries** that are stored at the connecting entity will be propagated through **Register** operation of the standard service specific interface.

2.3 Authorization

2.3.1 Client Authorization

This section extensively uses terms defined in "Security Framework of ARC1" document" [?].

To ensure information stored in ISIS cloud can't be tampered and only available to proper clients following authorization framework is implemented. All actions performed by ISIS clients are divided into three following groups:

- Operations initiated by other ISISes in the cloud. Those include:
 - Register with Registration Message containing information not about contacting client
 - RemoveRegistrations with request to remove Registration Message representing not contacting client
 - Connect indicating to provide every information about the stored database

Those operations may cause uncontrollable changes in collected information and must be granted only for highly trusted entities like ISISes themselves.

- Operations initiated by the Services registering to Information System. Those are:
 - Register with Registration Message containing information about contacting client
 - RemoveRegistrations with request to remove Registration Message representing contacting client
- Operations which are allowed for any liable client of particular Grid infrastructure.
 - Query
 - GetISISList

Those 3 action groups are handled using Security Framework of ARC [?]. For each group corresponding Action is defined for ARC policy language as described in table 2.1.

Table 2.1: ARC Policy Actions of ISIS

Group	Action	AttributeId
Request from ISIS	<i>isis</i>	http://www.nordugrid.org/schemas/policy-arc/types/isis/operation
Request from Service	<i>service</i>	http://www.nordugrid.org/schemas/policy-arc/types/isis/operation
Request from generic client	<i>client</i>	http://www.nordugrid.org/schemas/policy-arc/types/isis/operation

Access restrictions for clients are defined using ARC Policies which are specified and processed using generic Security Handlers approach. Corresponding Security Handlers have to be configured inside configuration block of corresponding ISIS service and attached *incoming* queue.

2.3.2 Information Authorization

Because all ISIS services trust each other they freely exchanging collected information. But not all information stored inside ISIS cloud is public or readable by clients authorized according to procedure described in section 2.3.1. There may be some pieces of information available only for specific clients. An example could be information about resources serving particular Virtual Organization (VO) could be visible only to members of that VO.

To implement functionality described above each node in aggregated XML documents of information collected by ISIS cloud may have Access Control Policy associated with it. Access control is defined at level of XML node and propagates all children nodes - similar to file systems. Children nodes can only additionally restrict access control imposed by parent node. For example if parent node A allows access only to VO1 then children node B can narrow access to Administrator of VO1 and can't grant access for VO2 members.

By default all XML nodes are public. Access Control Policies are embedded into XML document as XML nodes (see Appendix 4.4 for schema) even if that violates schema of document. Then nodes are assigned policies by adding XML attributes referring to defined Policies. Access permission to particular information node is evaluated by traversing all nodes from parent to children. At first node which gives negative result evaluation is stopped and this node including all its children is removed from document.

Before providing results of query operation ISIS runs procedure described above on results and also removes Access Control Policies. Reduced document obtained in this way is returned to requesting client.

2.3.3 Configuration

For information about sophisticated authorization policies and how to deploy various Policy Decision Point entities please see "Security Framework of ARC1" document" [?].

To restrict set of clients allowed to perform operations in ISIS service proper authorization policy is needed. Let's assume ISIS is operating over TLS connection and all participants possess X.509 certificates with following subject names:

- /O=Grid/O=Test/CN=CLIENT - generic client entities
- /O=Grid/O=Test/CN=SERVICE - generic service entities
- /O=Grid/O=Test/CN=ISIS - all ISIS belonging to ISIS cloud

In NO way we suggest to use such setup. Real installation should use more sophisticated way to identify clients contacting ISIS service. For an infrastructure with quite static roles distribution for example we suggest to use Virtual Organization Management Service (VOMS) attributes embedded into X.509 certificates representing participating entities.

Below is an example policy made of 3 rules defined in lines 4-17, 18-29 and 30-39. Those define allowed behavior for ISIS, generic service and generic client. Lines 6-7, 20-21 and 32-33 specify attributes used to recognise type of connecting client. In this case those are subjects of X.509 certificates with values defined above. Lines 10-15, 24-27 and 36-37 specify allowed actions. One can see that this policy allows all operations to be performed by ISIS client. It limits operations allowed for generic service to "service" and "client" types. And client entities are allowed to perform "client" type operations only.

```

1: <?xml version="1.0" encoding="UTF-8"?>
2: <Policy xmlns="http://www.nordugrid.org/schemas/policy-arc" PolicyId="policy1"

20:       <Subject AttributeId="http://www.nordugrid.org/schemas/policy-arc/types/tls/identity"
21:         >/O=Grid/O=Test/CN=SERVICE</Subject>
22:     </Subjects>
23:     <Actions>
24:      <Action AttributeId="http://www.nordugrid.org/schemas/policy-arc/types/isis/operation"

```

```

25:         >service</Action>
26:     <Action AttributeId="http://www.nordugrid.org/schemas/policy-arc/types/isis/operation"
27:         >client</Action>
28: </Actions>
29: </Rule>
30: <Rule RuleId="client_to_isis" Effect="Permit">
31:     <Subjects>
32:         <Subject AttributeId="http://www.nordugrid.org/schemas/policy-arc/types/tls/identity"
33:             >/O=Grid/O=Test/CN=CLIENT</Subject>
34:     </Subjects>
35:     <Actions>
36:         <Action AttributeId="http://www.nordugrid.org/schemas/policy-arc/types/isis/operation"
37:             >client</Action>
38:     </Actions>
39: </Rule>
40: </Policy>

```

This policy is not as restrictive as it could be in order to allow ISIS register themselves as ordinary services and to allow services which perform discovery of other services to behave like ordinary clients.

In order to activate policy it must be linked to ISIS service through Security Handle and Policy Decision Point emedded into configuration of ISIS. Below is minimal example configuration element of ISIS service. In lines 7-17 a set of Security Handler and Policy Decision Point is configured to handle policies written in ARC Policy Language (described in [?]). Line 14 specifies that policy is read from file */opt/arc/etc/isis/policy.xml* every time new request is arrived. If policy is not satisfied then ISIS returns SOAP Fault instead of usual informative response.

18: </Service>

```

Chapter 3

Service

3.1 Information generation

The service developers have to ensure that the services are providing the necessary information about themselves when registering to ISISes. This is done by implementing the subclass of the `Arc::Service` class - the `RegistrationCollector` function has to provide up-to-date status information about the service and anything else it wants to be advertised. This information package is called **Service Advertisement**. The **Service Advertisement** can contain any information service wants to advertise but the mandatory elements have to be always present:

- Service ID: A globally unique identifier of the service.
- Service Type: The Glue2 type of service.
- Endpoint URL: The URL where the service can be contacted provided as part of EPR element.

Because there may be multiple registration processes running in parallel it is important to ensure that implementation of `RegistrationCollector` is thread safe or there are internal locks implemented.

Every service registering to ISIS should also provide an interface for direct querying of information describing service. Normally this information should be more detailed than one sent to ISIS. For this purpose LIDI interface is defined which is a subset of WS Resource Properties (WSRP) [?]. Following WSRP operations must be supported - *GetResourcePropertyDocument*, *GetResourceProperty*, *GetMultipleResourceProperties* and *QueryResourceProperties*.

3.2 Registration

The registration of service is carried out by internal module called Registrant. The Registrant is active module of the HED (Hosting Environment Daemon) which is bound to a set of ISISes. In practice, the configuration part of the Registrant contains exactly one ISIS to bind, and the Registrant will collect the necessary information about the other ISISes belonging to the same network.

To register services to more than one ISIS network multiple Registrant instances has to be configured. In this case, the default Registrant will be used for registering every services unless configured explicitly. The registration of service can be done once or periodically based either on the configuration of the Registrant or overwritten for every service separately. The Registrant is also performing message aggregation of all services linked to it if possible. The simplified algorithm of the Registrant is presented below.

Registrant - pseudo algorithm

```
// Initialize phase
Read the configuration and store the information about the services in a list
```

```

do { // Cyclic phase in a different Thread
    wake_up_time = now();
    messages = null;
    if ( 0 < count(service where service.next_run <= wake_up_time)) {
        foreach( service where service.next_run <= wake_up_time) {
            messages.add(service.RegistrationCollector);
            service.next_run = wake_up_time + service.period;
        }
        if (0 < count(messages)) {
            sent_message = assemble message with headers(messages);
            send(sent_message);
        }
    } else {
        sleep(min(service.next_run) - now());
    }
} while(true)

```

Current implementation does not allow value of the period to be less than 2 minutes.

Service provides **Service Advertisement** part of information sent to ISIS (see Section 2.1.2). Before sending this information the Registrant extends it with additional data (**Service Advertisement Metadata**).

An example layout of services is shown on Figure 3.1. In this configuration example there are two Registrants configured in one HED container for three services. The *Registrant A* is the default Registrant and the services configured in the following way:

- Service 1: There is no Registrant configured so the default one will register it.
- Service 2: The *Registrant A* is configured explicitly.
- Service 3: The *Registrant B* is configured explicitly.

So the Service 1 and 2 are handled both by *Registrant A* and Service 3 by *Registrant B*. In the first step each Registrant performs information collection from all assigned services sequentially. Registrants themselves are executing in parallel. For Figure 3.1 the approximate sequence of information collection is (*A1-A2*, *B1-B2*) followed by (*A3*, *A4*). After collection the aggregated information is sent to the corresponding ISISes independently by each other Registrant (*A5*, *B5*).

Figure 3.1: Overview of the registration process

This registration operation is done once during the start-up phase and periodically according to (per service) configured periods.

3.3 Authorization

For each information provided by service through the LIDI interface same procedure as described in Section 2.3.2 should be applied.

3.4 Configuration

The registration operation is done by the Registrants as described in Section 3.2. Each Registrant is instantiated by corresponding InfoRegistrar XML element in configuration file as defined in Section 4.3. First InfoRegistrar defines Registrant which is used to register every service by default.

Registration parameters per service are defined by InfoRegister element located inside corresponding service configuration element. To assign service to specific Registrant(s) one may use Registrar configuration elements situated inside InfoRegister. If none Registrar element is defined service will be registered using first (default) Registrant. To make not register itself special configuration element NoRegister has to be used.

Following elements are defined inside configuration element of the Registrant:

URL specifies contact endpoint of a bootstrap ISIS. If needed further ISIS addresses will be queried from this service. This element is mandatory.

KeyPath, CertificatePath, ProxyPath and CACertificatesDir are paths to files storing X509 credentials used for establishing connections. Those elements are optional and needed only if TLS communication is used.

Retry specifies how many times communication to ISIS have to fail/timeout to start treating it as unavailable. The default value is 5.
